The Institute for the Study of Labor (IZA) in Bonn is a local and virtual international research center and a place of communication between science, politics and business. IZA is an independent nonprofit company supported by Deutsche Post World Net. The center is associated with the University of Bonn and offers a stimulating research environment through its research networks, research support, and visitors and doctoral programs. IZA engages in (i) original and internationally competitive research in all fields of labor economics, (ii) development of policy concepts, and (iii) dissemination of research results and concepts to the interested public.

IZA Discussion Papers often represent preliminary work and are circulated to encourage discussion. Citation of such a paper should account for its provisional character. A revised version may be available directly from the author.

ABSTRACT

Self-Employment Dynamics Across the Business Cycle: Migrants Versus Natives*

Economically active people are either in gainful employment, are unemployed or self-employed. We are interested in the dynamics of the transitions between these states across the business cycle. It is generally perceived that employment or self-employment are absorbing states. However, innovations, structural changes and business cycles generate strong adjustment processes that lead to fluctuations between employment and self-employment, directly or through the unemployment state. Migrants are more likely to be sensitive to adjustment pressures than natives, since they have less stable jobs and choose more often self-employment to avoid periods of unemployment. These issues are investigated using a huge micro data set generated from 19 waves of the German Socio-economic Panel. The findings suggest that the conditional probabilities of entry into self-employment are more than twice as high from the status of unemployment as from the status of employment. Self-employment is also an important channel back to regular employment. Business cycle effects strongly impact the employment transition matrix, and migrants take a larger part in the adjustment process. They use self-employment as a mechanism to circumvent and escape unemployment and to integrate into the host country's labor market.

* Presented at the 2004 meeting of the Society of Labor Economists (SOLE) in San Antonio and at the 2004 Western Economic Association Annual Meeting in Vancouver. We wish to thank conference participants including Holger Bonin, Robert W. Fairlie, and Don Williams for valuable comments. The GSOEP data used in this study are available upon request from the German Socio-Economic Panel at DIW Berlin (www.diw.de/gsoep). The paper has also benefited from a research visit of Amelie Constant to DIW Berlin in the Fall of 2004.

1. Introduction

There are two types of entrepreneurship: First, there are those individuals who freely choose an independent profession that enables them to materialize their visions. They face risky choices, but this is part of their success strategy; they are pulled or attracted by the lucrative facets of self-employment. Second, there are those forced to work on their own risk because nobody else wants to take the risk to employ them. The latter are often either the former unemployed or immigrants and ethnic minorities, who use this activity as a channel of circumventing or escaping from long-term unemployment or as a means to climb up the employment ladder into regular employment. Forced self-employment, however, does not exclude the fact that these individuals are industrious and venturesome. It is important to note that these push-pull scenaria depend on the phase of the business cycle. Empirically, it is difficult to separate these two types of self-employed individuals in a static data setting due to the lack of appropriate panel data.

Therefore, the focus of this paper is to contribute to this under-researched area by investigating the dynamics of self-employment using a rich and long panel micro data set for Germany. In the German context immigrants and ethnic minorities are difficult to separate, however. Hence, due to the nature of our data, we jointly investigate the behavior of more recent immigrants and those who still carry the foreign passport and compare them with the dynamic behavior of natives when confronted with the ups and downs of the business cycle. To introduce our research approach, we first outline the relevant literature on the self-employment of natives, immigrants and ethnic minorities and the related results associated with the business cycle.

While the prevalence of self-employment among immigrants, ethnic groups in general and natives in the labor market has been researched and documented by many studies in the US, research on entrepreneurship and especially immigrant or ethnic entrepreneurship in Europe and Germany, in particular, has been somewhat scant. Recent surveys on the rising empirical literature on self-employment in a comparative setting investigating research in the US, Europe, and other

immigration countries include Le (1999), Blanchflower, Oswald and Stutzer (2001), Audretsch (2002), Audretsch, Thurik, Verheul and Wennekers (2002) and Blanchflower (2004). These studies, mostly cross-sectional, identify the role of managerial and other individual abilities, gender, education, family background, occupational status, financial constraints, the nature of work, and ethnic enclaves, among other factors as relevant determinants of self-employment.

Borjas (1986) finds that the probability of self-employment of migrants increases with years since migration in the US, and that recent immigrant cohorts have higher self-employment rates than earlier cohorts. Living in enclaves also increases self-employment probabilities. Compared to similarly skilled native-borns, immigrants are more likely to be self-employed. Other outstanding work for the US includes the paper by Fairlie and Meyer (1996); this comprehensive study of ethnic/racial groups by gender presents tests of many theories and provides evidence that individuals are pulled rather than pushed into self-employment. That is, self-employment is appealing to ethnic groups because of its high relative returns rather than it is the outcome of discrimination or language difficulties. However, a panel study on black and white men in the US finds that blacks are severely underrepresented in self-employment, and the self-employment ratio between blacks and whites has been constant over the last 80 years at one to three (Fairlie 1999). The paper goes beyond looking at determinants of self-employment by calculating dynamic transition probabilities between self-employment and paid employment, both for entry and exit; transition rates differ substantially by race. By decomposing the racial gap in the transition rate in and out of self-employment this study finds, however, that education, assets, and father's self-employment explain part of the racial gap in entry rates but not in exit rates.

There is only scarce evidence about migrant entrepreneurs in Europe and especially in Germany. The findings by Clark and Drinkwater (1998) suggest that self-employment is a way out of discrimination in paid employment for immigrants in Great Britain. Wage work pays less well for ethnic minorities when they are compared to natives, and the difference has increased over time. The increase in the earnings disadvantage is correlated with a rise in the self-employment of ethnic

minorities. Although there are higher self-employment rates for non-whites than for whites, one nevertheless observes a substantive variance among the ethnic groups. Most ethnic minorities also earn less in self-employment than similar self-employed whites.

For Germany, Constant, Shachmurove and Zimmermann (2003) find that the probability of self-employment increases significantly with age for all groups albeit at a decreasing rate. While Turks are twice as likely to choose self-employment as any other immigrant group, their earnings are no different than the earnings of the other self-employed immigrants. The age-earnings profiles of self-employed native and immigrant men are concave and surprisingly similarly shaped. While for self-employed German men hours of work and Treiman prestige scale increase their earnings, for self-employed immigrant men it is the longevity of the business that makes a difference.

Constant and Schulz-Nielsen (2004) find that self-employment rates among ethnic groups vary widely with ethnicity and sex, and that many refugees are in self-employment. Self-employed immigrants in Germany are self-selected with respect to human capital, age, years since migration, family background characteristics, homeownership, and enclave living. Iranians and Lebanese are more entrepreneurial than Turks. Self-employed immigrants also earn twice as much as immigrants in paid employment, while those immigrant entrepreneurs of younger age, who own a larger size business and live outside ethnic enclaves, have higher earnings. In Denmark, however, it is only the males and those with disabilities who are self-selected into self-employment. While Iranians are still more entrepreneurial than Turks, the ex-Yugoslavs are not. Overall, in Denmark, immigrant entrepreneurs earn less than immigrants in paid employment. This comparative study of the same immigrant groups in two host countries observes that maybe some countries are not conducive to self-employment and that self-employed immigrants in Denmark, for example, would find a better match for their talents if they were to move to Germany.

The literature on the business cycle effects on self-employment around the world uses unemployment rates as a proxy for the business cycle, and produces rather conflicting evidence. Some studies find that self-employment is inversely related to business fluctuations and it lags in

response to recession (see Aronson 1991 for a review). In a panel study on the OECD countries, Blanchflower (2000) also finds a negative relationship between self-employment and unemployment rates. In contrast, Evans and Leighton (1989) in their longitudinal study on white men in the US find a positive relationship between self-employment entry and unemployment rates, supporting the push theory. Using longitudinal data for men in Spain, Carrasco (1999) also finds that the unemployed are more likely to switch into self-employment, and this likelihood is increasing with the availability of assets, more education, and older age. The switch is more attractive for the unemployed when the economic situation improves.

Moore and Mueller (2002) find, among other things, that self-employment decisions are independent of the situation in the labor market as measured by the unemployment rate. Still, their results are more consistent with the push theory. Yet, Robson's (1998) study, based on various sources of aggregate data in the UK, finds no "recession push." Another panel study on males in Denmark concurs on the very different labor market transition patterns between natives and immigrants, and finds strong differences among the immigrant groups; immigrants from less developed countries are marginalized self-employed who use the self-employment option as a last resort (Blume, Ejrnæs, Skyt Nielsen, and Würtz 2003).

Our paper is unique in that it uses a rich panel data set that allows following the employment and unemployment paths of individuals and identifying their status over long enough periods to capture business cycle effects. The data set employed is from the first 19 years of the German Socio-Economic Panel with rich information on both natives and immigrants. The perceived employment, self-employment and unemployment history, individual indicators of economic performance and the macroeconomic conditions in general are used to determine the status of forced self-employment. This is modeled against the genuine type of entrepreneur, who is identified by ethnic status, parental entrepreneurial human capital, state-dependence, and individual educational performance. We use GNP growth instead of macro unemployment rates to identify business cycles because unemployment rates in Germany vary asymmetrically.

We concentrate on males who are in the active labor force. Hence, the core employment states are employed, self-employed, or unemployed. Unlike most other studies, we include the registered as unemployed as an empirically distinct state in the labor market.¹ At any time, there is a transition matrix describing the conditional probabilities of moving from the current to the next period's state vector. We explore the short-run and the long-run versions of the transition probability matrix that capture the core employment dynamics.² We model the transition probabilities using rich panel data that capture individual behavior and merged information on the macro business cycle. We expect business cycles to generate adjustment processes that lead to fluctuations between employment and self-employment, directly or through the unemployment status. Migrants or ethnic groups are more likely to be sensitive to adjustment pressures than natives, since they have less stable jobs and choose more often self-employment to avoid periods of unemployment. Hence, we want to understand how ethnicity and business cycle effects act and interact with the employment transition probabilities.

The paper is organized as follows: In Section 2 we outline the Markov modeling strategy of transitions between the core employment states, namely employment, unemployment or self-employment, and the empirical estimation of the respective transition probabilities through multinomial logit models. In Section 3 we explain the data set, describe the construction of the variables employed, and present the basic hypotheses for our empirical study. In Section 4 we present the business cycle and self-employment trends over the last 20 years in Germany, the characteristics of the sample used, and explore the cyclicity of the transition probabilities. Section 5 examines the econometric evidence on the dynamics between the core employment states. Lastly, Section 6 summarizes the paper and concludes.

¹ The registered as unemployed have a different behavior than the not employed, who are not attached to the labor force. While there are significant transitions from unemployment to employment, the transition from no employment to employment is very low (Flinn and Heckman 1982).

² Such a computable Markov chain model has recently been proposed and applied by Constant and Zimmermann (2003) to issues of circular migration in Germany.

2. Model Specification

2.1. A Markovian Modeling Framework

We model the movement of individuals between the employment states by a discrete-time discrete-space Markov process. We assume that the employment status of the individual at any period t is described by a stochastic process $\{E_t\}$ that takes values in a finite discrete state space $S = \{0, 1, 2\}$. A Markov chain is a sequence of random values whose probabilities at a time interval depend upon the value of the number at the previous time (Papoulis 1984). We embody the idea that if an individual knows the current state, it is only this current state that influences the probabilities of the future state. At each time, the Markov chain restarts anew using the current state as the new initial state. We assume that this Markov chain has three states, 0, 1, and 2 indicating that an individual is employed, unemployed or self-employed respectively. The vector containing the long-term probabilities, denoted by π , is called the steady-state vector of the Markov chain.

The state probability (row) vector is:

$$\pi = [\pi_0, \pi_1, \pi_2] \quad (1)$$

where π_0 , π_1 , π_2 are the probabilities that a person is in employment, unemployment, or self-employment. Under the assumption that the system converges and is in steady-state, the state probabilities do not depend on the year of observation. This is the stationary distribution of the chain and satisfies the following equation:

$$\pi = \pi * P \quad (2)$$

where

$$P = \begin{pmatrix} p_{00} & p_{01} & p_{02} \\ p_{10} & p_{11} & p_{12} \\ p_{20} & p_{21} & p_{22} \end{pmatrix} \quad (3)$$

is the transition probability matrix with $P_{00} + P_{01} + P_{02} = P_{10} + P_{11} + P_{12} = P_{20} + P_{21} + P_{22} = 1$. P_{00} is the probability that a person who is employed in the current year would tend to stay in this category of employment in the next year, while P_{01} is the probability that a person who is employed in the current year would tend to move to unemployment in the next year, and P_{02} is the probability that a

person who is employed in the current year would tend to move to self-employment in the next year, and so on.

A transition probability is the commanding factor in a Markov chain. It is a conditional probability that the system will move to state 0, 1 or 2 in the next time period, given that it is currently in state 0; it will move to state 0, 1 or 2 in the next time period, given that it is currently in state 1; and it will move to state 0, 1 or 2 in the next time period, given that it is currently in state 2. The Markov chain obtains the much desired efficient estimates when the transition probabilities are properly determined. Even if the system converges in the long run, the Markov chain equation does not need to hold in the short run. However, if this equation is closely applicable with real data this indicates that the Markov assumption is useful in describing reality.

We assume that individuals have a myopic but pragmatic foresight (taking it one step at a time) and maximize their utility at every period given the state they are currently at. We assume a discrete time process where a person's status is a random process in time. The Markov approach is, then, an appropriate representation of the structure of the behavioral process of individuals who move in between employment states. The key feature of this model is that the future state depends solely on the current state.

Specifically, the transition probabilities of an individual m from one state to the other or to the same state depend only on the current state, and the socioeconomic characteristics of the individual, X_m . These independent variables are expected to affect the individual's probability of being in a given state. We consider six distinct outcomes that describe the transitions. Transitions to the same state, that is, from state 0 to 0, 1 to 1, or 2 to 2, are not considered here. This is convenient since the summing-up restrictions of conditional probabilities allow us to exclude three conditional probabilities, and we concentrate on transitions to different types of employment.

2.2. Modeling the Steady State Transition Probabilities

To estimate the transition probabilities as they are explained by the individual characteristics, X , we employ three multinomial logits conventionally specified as:

$$P_{ij} = \frac{e^{\beta_{ij}'x_i}}{\sum_{m=0}^2 \sum_{n=0}^2 e^{\beta_{mn}'x_i}} \quad 0 \leq i, j \leq 2 \quad (4)$$

The idea is that individuals have three choices depending on the state there are in. We estimate a multinomial logit on the probability to go into unemployment or self-employment, given that the individual is currently in paid employment. Second, we estimate the probability to go into paid employment or self-employment, given that the individual is currently in unemployment. Third, we estimate the probability to go into paid employment or unemployment, given that the individual is currently in self-employment.

The closed form for the probability that a person will move from one state to the other from time t to $t+1$ is:

$$P(Y = j | X) = \frac{e^{\beta_j X_i}}{1 + \sum_{k=0}^{K-1} e^{\beta_k X_i}} \quad (5)$$

where i indexes the individuals, and j indexes the alternative transitions: $j = 0, 1, 2$, which are three nominal, unordered outcomes. To identify the model, we impose the normalization $\beta_0 = 0$. The characteristics in X will help us explain how a person evolved into getting to that specific state and how his choice is influenced for the next move. Lastly, we calculate the steady state probability vector (π) to find the probability that an individual is in a certain state.

3. Data Source, Variables and Hypotheses

3.1. The GSOEP and Construction of the Sample

The German Socioeconomic Panel (GSOEP), administered by DIW Berlin, is a nationally representative annual survey (see SOEP Group 2001) that started in 1984 in the former Federal Republic of Germany with a sample of about 12,000 respondents, 3,000 of whom were legal

immigrants. The latter were those living in a household whose head was from Italy, Greece, Spain, Yugoslavia, or Turkey - the migrants and descendants from the so-called guestworker regime. The GSOEP is an ongoing longitudinal database that interviews all persons aged 16 or older. It contains rich socioeconomic information on both native Germans and legal immigrants. The GSOEP actually oversamples guestworkers and, additionally, provides excellent information on their pre-immigration experiences. In this long-term analysis we do not include the collected data on East Germany after unification and the other various refreshment samples created since then. We concentrate on native West Germans and legal immigrants (or guestworkers) who have been living side by side in the former West Germany for more than 30 years.

We use 19 waves of West German data during the period 1984 - 2002. We focus on the male subsample because men are characterized by a strong labor market attachment, and their employment transitions are more cleanly related to labor market structures and the business cycle. Our sample contains all males over 16 years of age who were successfully interviewed and available in a transition between two consecutive years in the states employed, unemployed or self-employed. The upper cut-off age is 60 to avoid any spurious effects due to retirement decisions. We also exclude those in the military, the students, and the civil servants. This longitudinal sample contains 7,652 individuals, of whom 2,462 are immigrants and 5,190 are native West Germans. Table 1 presents the yearly sample observations and the final longitudinal sample by ethnicity.

To implement the event history analysis we restructured the GSOEP data into “person-years,” which became the effective unit of our analysis. A person-year is a one-year fraction of a person’s life during which the event in question (a move to another employment status) may or may not occur. Each yearly fraction of a person’s life is treated as a distinct observation. The person-year file contains information about the occurrence or nonoccurrence of the event, as well as the values of relevant independent micro- and macroeconomic variables (with or without temporal variation); it is the life history of each person. However, it is not necessary that every person experiences the event. In our analysis, however, we only consider complete transitions from one

state to the other. The Markov modeling rationale keeps those individuals who are out of the labor force out of the analysis. This implies a two-stage decision process where a first stage models the probability to enter the labor force, and a second stage deals with the probability to enter into one of the three states (employment, unemployment and self-employment).

The person-year file has 62,780 observations, representing detailed longitudinal histories of the individuals' experiences and behavior from the moment they enter the sample until exit, death, or the final survey date. The variables we employ in our analysis may either be fixed or time-varying. The variables that change from year to year include age, years since first arrival in Germany and GNP growth rates. We use GNP growth instead of macro unemployment rates as in the literature to identify business cycles since unemployment rates in Germany vary asymmetrically across the cycle. Those variables that are referring to fixed characteristics, such as education before migration and ethnicity, remain constant over person-years.

To capture all transitions in the most accurate manner, we initially consider and keep the individuals who are not in the labor force in any current state because they might change and go into the labor force in the future state. After we calculate the complete transitions, we delete the not employed and continue our analysis with those in the labor force. The final person year file has 47,961 observations with 32,880 native West Germans, and 15,081 immigrants.

3.2. Variables and Hypotheses

To effectively capture the cyclical dynamics of our transition probabilities we control for both micro- and macroeconomic variables. First, we control for the standard forms of human capital, family characteristics, intergenerational links, demographics, and ethnicity. We augment the model with the GNP growth rates and an interaction variable between GNP and ethnicity.

The human capital variables are separated into schooling acquired in Germany and in the home country for the immigrant group. Besides formal schooling we employ vocational training (both pre- and post-migration) because this is a unique feature of the German educational system

and makes a difference in the labor market placement and opportunities. For formal schooling in Germany we consider three categories: (i) no schooling degree, which is the reference category, (ii) primary or lower secondary schooling, and (iii) high school and beyond. Graduating with vocational training in Germany is a separate dummy variable.

For immigrants, we create two additional dummy variables for pre-migration formal schooling and vocational training. We expect that individuals with more schooling and vocational training will have lower chances in going into unemployment if they are working, and higher chances in going into employment or self-employment when they are unemployed. As a proxy for the health status of the individual (a vital form of human capital), we create a dummy variable from the occupational disability question.

The age and years since migration variables capture experience, savvy, and know-how of the labor market; they are entered as quadratics. In principle, these variables should have a differential impact on all three employment choices. For age, for example, we expect that older individuals are more likely to go into self-employment from employment, because older workers have more experience, know the market better and face lower liquidity constraints. For years since migration, we expect that immigrants who are newcomers in Germany will be more likely to go into unemployment because they are in a more precarious condition. On the other hand, the longer immigrants are in Germany the more likely they are to go into self-employment or employment.

Marital status and young children in the household can also affect labor market choices and sorting. Married men and men with young children, as income earners and household providers, will be less likely to go into unemployment and more likely to stay employed either in paid- or self-employment. Homeownership is expected to affect the employment transitions as well. Individuals who own their house will be more likely to stay employed. The “father self-employed” variable captures intergenerational links. Self-employed fathers can pass on to their children an invaluable lore. According to the literature, there is a strong intergenerational link from fathers to sons, especially in the self-employment sector (Dunn and Holtz-Eakin 2000). We expect that men whose

father is self-employed will be more likely to go into self-employment from other states, and to choose self-employment as their steady absorbing state.

The next group of independent variables refers to the nationality status. We distinguish individuals as native West Germans and immigrants. Within the immigrants we differentiate among Turks, individuals from the former Yugoslavia, Greeks, Italians, and Spaniards. Because the low number of observations of self-employed Spaniards rendered our model inestimable, we regrouped the ethnicity variables of Greeks, Italians, and Spaniards into the “EU” variable, since all these groups are part of the European Union for a long time and share a common legal status in Germany. We expect that different nationalities have different paths in the labor market. Some groups for example, may be more entrepreneurial than others, some have long traditions in self-employment, and some may be more affected by structural changes. The reference category is native West German men.

We lastly control for business cycle. Employment transitions could be pro- or countercyclical, as they could also be acyclical. Unlike other studies, we employ the GNP growth rates, as the capstone of the statistics on business cycle. For the analysis on the entire sample, we also create an interaction variable between GNP growth rates and ethnicity to see whether the business cycle affects immigrants differently. This variable also goes to the asymmetrical effects created by the business cycle. We finally adjust the econometric model using robust standard errors. Because immigrants may differ from natives, we repeat this exercise for immigrants only. In this analysis, the reference ethnic group is the Turks. Empty cells problems forced us to exclude the “disability” and “father self-employed” variables from the self-employment estimation.

4. Business Cycle, Sample Characteristics and Transition Probabilities

4.1. Self-employment Trends and the Business Cycle

All countries experience business cycles or economic fluctuations due to economic disturbances of various sorts. In general, a business cycle has 4 phases: the downturn (recession or contraction), the

trough, the upturn (boom or expansion), and the peak. Contrary to the word “cycle” these phases are not always regular in their periodicity, amplitude, duration and timing. While there is some consensus on the effect of business cycles on employment (for example, during a recession employment falls and unemployment rises while during expansion employment rises and unemployment falls), the effect of business cycles on self-employment per se are not as clear-cut.

In general the arguments can be summarized as follows. Individuals can be either pushed or pulled into self-employment depending on the phase of the business cycle. Those who are unemployed or not employed and cannot easily find paid employment during a recession phase could use the self-employment state as a means of circumventing unemployment and hardship in the labor market. In that case one would expect self-employment rates to increase during the downturn and individuals to be pushed into forced self-employment. However, the success and longevity of a business is rather low during the downturn, which in turn, can also act as a deterrent to self-employment start-ups.

During the expansion phase, individuals who are unemployed or not employed can easily find paid employment. They may, thus, be more likely to choose the more “secure” avenue of paid employment than self-employment. At the same time, self-employed individuals may also close down their business³ and find a better and “secure” job by working for somebody else in the expansion phase. It is possible, thus, that self-employment rates are lower during a boom. On the other hand, many individuals can be pulled into self-employment during the expansion phase because it is easier to establish or expand a business and increase profits. Self-employment becomes less risky in this case. We would, thus, expect that self-employment rates increase with a boom.

Using official statistics (Sachverstaendigenrat 2003) we calculate the growth rates for GNP from 1983 – 2003, encompassing the entire period of our sample. Similarly, we calculate the growth rates for self-employment in Germany during that same period. The results of these

aggregate statistics are plotted in Figure 1. This figure shows that GNP was on a downturn from 1984 to 1987, where it reached its trough. This downward trend was severely amplified in the self-employment trend, which - after reaching its peak in 1984 - dipped to its lowest and negative level in 1986. Self-employment increased dramatically, however, in 1987 although GNP was decreasing.

From 1987 to 1990 there was an overall uptrend and GNP was growing. The peak of the German expansion phase occurred in 1990. The corresponding self-employment growth rates show that they are closely following and matching the GNP growth rates but only when the latter follows a sustained growth. For short period bumps and dips, self-employment rates exhibit a countercyclical pattern. Nonetheless, self-employment growth rates stayed below GNP growth rates.

After the German reunification in 1990, GNP started declining with a pronounced precipitous and severe drop after 1991. GNP reached a trough with negative levels in 1993. While self-employment rates match the precipitous decline of the GNP in the beginning, especially during the period 1988-1992, and mimic every move of the GNP from below, they bounce back up in 1992 in a procyclical manner, overshooting the GNP growth rates.

The recovery period of the business cycle started after 1993, and GNP reached positive levels again in 1994. With the exception of a small dip in 1996, GNP kept growing to reach another peak in 2000. Up until 1998 of this recovery and expansionary period, self-employment rates exhibit strong procyclical patterns, and stay at positive levels always from above of the GNP. After 2000 GNP starts its downturn, and self-employment follows the same route from below. As it can be seen from Figure 1, the self-employment growth rates follow largely the GNP growth rates, although not always closely.

³ If the business does not take off the way entrepreneurs want it, it is easier for them to close it down and move into paid employment.

4.2. Characteristics of our Sample Population

In [Table 2](#) we present the means of the relevant individual characteristics by employment state and nationality. On average, the youngest workers are in paid employment, while the oldest workers are in self-employment. The average self-employed German in our data set is 42 and the average immigrant is 39 years old. For immigrants, we also report their length of stay in Germany. Overall, for every state, immigrants have been living in Germany for more than 20 years. [Table 2](#) shows that the longer the immigrants are in the host country, the more likely they are to be in the self-employment category, while the shorter time they have been in the host country the more likely they are to be in paid employment.

When we compare the three groups of employed, unemployed and self-employed in the entire sample, we find the largest share of individuals with no schooling degree among the unemployed (15%). Those individuals have a much lower share among the employed (9%) and among the self-employed (4%). Among the unemployed, more than a quarter of the immigrants have no schooling degree in Germany. Since this variable is not conditional on age, the high non schooling rates of immigrants could be due to their entry at an older age. The smallest share of uneducated men is in the self-employment category (1%). For immigrants, we find almost equal fractions of the individuals with high school and beyond in the self-employment (58%), unemployment (51%) and employment categories (54%). For Germans, the fractions of individuals with high school and beyond are 53% in the self-employed category, 41% among the employed and 25% in the unemployment category. Similarly, we find that individuals with vocational training in Germany have a high presence in the work categories: 68% of the self-employed and 67% of those in paid employment in the entire sample have a vocational training degree. Among the unemployed immigrants, only 33% have vocational training, while more than 40% do have such a degree in the employment and self-employment categories. Migrants with pre-migration schooling are more equally dispersed across the categories; about 50% of the employed and the self-employed have some schooling degree from their home countries, but only 48% of the group of the unemployed.

Similarly, 30% of the employed and the self-employed have vocational training in their home country, but only 25% of those migrants who are unemployed.

We find that individuals with impaired health status have the strongest presence in the unemployment category; their presence is lower among the employed men and lowest among the self-employed. Overall, immigrants in all groups exhibit a lower share of individuals with a disability status than Germans. Homeowners are strongest in the self-employment category (57% in the entire sample, 63% of the natives and 25% of the immigrants). Among the employed, 49% of the Germans own their home, but only 13% of the employed immigrants. Still 34% of the unemployed Germans own a home, but only 8% of the unemployed immigrants are homeowners.

In Table 2 family characteristics are measured by marriage status and the presence of small kids. Immigrants have more family presence among all three states than natives. In the unemployment category, immigrants and Germans have lower shares of individuals with family characteristics than in the other two states. These findings are consistent with the well-established fact that being married and having small kids create a positive impact on economic performance for men.

Looking at the ethnicity groups, we see that German men have the strongest presence in the self-employment category; 84% of the entrepreneurs, but only 68% of the employed and 55% among the unemployed are Germans. In contrast to Germans, immigrants have lower shares in self-employment. Turks, have the highest share in the unemployment category (24%). Turks have also the highest unemployment share among all immigrants (54%). While 12% of those in paid employment are Turks, their share in the self-employment category is only 4%. In the group of the self-employed, immigrants from the former Yugoslavia have a rate of 3%, their share being 7% among the unemployed and those in paid employment. The three nationalities that compose the EU immigrants exhibit a comparatively higher share among the self-employed than the other immigrants (9%). About 14% of the immigrants in paid employment and unemployment nationals are from the EU.

4.3. Transition and State Probabilities

In [Table 3.1](#) we present the average transition probabilities calculated experimentally from the raw data for the entire sample. This table shows that the relevant transition probabilities are $P_{01} = 0.033$, $P_{02} = 0.011$, $P_{10} = 0.329$, $P_{12} = 0.025$, $P_{20} = 0.071$, $P_{21} = 0.009$. The probability of the transition from employment to unemployment is 3%, while the transition to self-employment is at a low 1%. The probability of the transition from unemployment to employment is a high 33%, while the move from unemployment to self-employment is only 2.5%. Conditional on being unemployed the transition probability into self-employment is 2.5 times higher than into being employed. The probability to move from self-employment to employment is at a high 7%, while the transition probability from self-employment to unemployment is at a very low 1%.

Next, we find that the average initial state distribution vector π - calculated from the raw data - is $\pi = [\pi_0 \quad \pi_1 \quad \pi_2] = [0.837 \quad 0.066 \quad 0.096]$. Applying the Markov chain equation the calculated estimates of the steady state probabilities after the transition are: $\pi^* = [0.829 \quad 0.072 \quad 0.100]$; this is nothing else than the average state probabilities from the raw data after the transition. These numbers are sufficiently close to π to make us believe that the Markov chain specification is an appropriate representation for our employment transition setting.

The average transition probabilities for immigrants are presented in [Table 3.2](#). The numbers along the diagonal show that the highest tendencies are to stay in employment, unemployment, and self-employment from the respective current states. The transition from employment to self-employment is the lowest (0.8%) indicating that immigrants are not moving into self-employment often. The probability from self-employment to employment is high at 10%. That is, the exit probabilities are 10 times higher than the entry ones. The probability from unemployment to employment is 32% while the probability to self-employment is only 1%. The state probability estimations for the immigrant sample are as follows: $\pi = [\pi_0 \quad \pi_1 \quad \pi_2] = [0.854 \quad 0.095 \quad 0.051]$ and $\pi^* = [0.844 \quad 0.104 \quad 0.053]$. We can safely say that π and π^* are sufficiently close.

The average transition probabilities for Germans are presented in Table 3.3. When compared to the transitions of the immigrants in Table 3.2, Germans move less strongly from employment to unemployment. Their transition probabilities from unemployment to self-employment are more than twice as large as those of the immigrants. And the transitions from self-employment to employment and to unemployment are somewhat stronger for immigrants than for Germans. The corresponding estimation of the state probabilities for the German sample is as follows: $\pi = [\pi_0 \ \pi_1 \ \pi_2] = [0.830 \ 0.053 \ 0.117]$ and $\pi^* = [0.822 \ 0.057 \ 0.121]$. Once again, these numbers encourage us to believe that the Markov approach is good model for our data.

In Table 4 we present the correlation coefficients of the transition probabilities with the business cycle and among themselves over time. This analysis examines how the transition probabilities move over time with the ups and downs in the economy, and how they interact with each other. The first row pertains to the entire sample, the lower triangle pertains to the immigrant sample, and the upper triangle pertains to the German sample. Clearly, for the entire sample, the highest positive correlation is between the business cycle (GNP) and the transition from unemployment to paid employment (P_{10}). This confirms the expected outcome that in an expansion phase, workers go out of unemployment; however, their preferred state is in paid employment rather than in self-employment, given that they are unemployed. Nevertheless, there is some positive correlation between the business cycle and the transition from unemployment to self-employment: the better the economic situation is, the more the unemployed are also willing to become self-employed. The positive correlation between the business cycle and the transition from self-employment to employment is high as well. This indicates that during the upswing, workers leave self-employment for paid employment.

For immigrants specifically (lower triangle), we find a positive and very high correlation between the upswing of the business cycle (GNP) and the transition from unemployment into paid employment (P_{10}). The positive high correlation between P_{20} and P_{10} suggests that immigrants gravitate jointly into paid employment either when they come from unemployment or self-

employment. On the other hand, the correlation between P_{21} and P_{20} indicates that the transition probabilities for immigrants from the self-employment state for paid employment or unemployment move together over time. It is also interesting to see that the transition probabilities of moving from employment to unemployment P_{01} and from employment to self-employment P_{02} are strongly and positively correlated, which suggests that self-employment is an alternative to unemployment.

For German workers, we find a high correlation between GNP and P_{01} . This correlation is negative, suggesting that German workers are hit by the downturn of the business cycle and become unemployed. Similar to immigrant workers, the correlation between P_{20} and P_{10} is high echoing gravitation towards paid employment. Notable differences with immigrants go to the correlation between P_{01} and P_{02} and between P_{02} and P_{10} . The first indicates a strong transition out of employment, while the latter indicates a transition out of unemployment into self-employment through paid employment.

In [Figures 2-4](#) we illustrate the key annual transition probabilities for the 1984 - 2001 period for the entire sample. These figures are calculated from our microdata set. [Figure 2](#) shows the transitions from employment to both unemployment and self-employment. Clearly, there is not much movement between employment and self-employment. Overall, this transition probability remains low and hovers around 0.01, indicating that entry into self-employment from paid employment is not the preferred route of our sample population. Compared to GNP growth rates in [Figure 1](#), this figure displays a rather acyclical pattern. However, the transition probability from paid employment to unemployment exhibits a lot more variation and largely follows the business cycle.

We display the transition probability from the state of unemployment to self-employment in [Figure 3](#). This probability is also low but it has an interesting pattern. While it stays rather flat until 1990, it exhibits many ups and downs after that. This indicates that our sample frequently uses the self-employment option to exit unemployment. The transition probability from unemployment to employment, however, exhibits sharp variations and a worrying pattern: the probability to go back

into paid employment from unemployment keeps decreasing over the years, alluding to the increasing unemployment rates in Germany. Although there is significant entry and exit, individuals in our sample tend to stay in unemployment rather than move to paid employment. In fact, even during the booming years 1999-2000 this transition probability severely decreases.

The transition probabilities from self-employment to both unemployment and paid employment are illustrated in [Figure 4](#). These transitions show that there is considerable movement between self-employment and paid employment, indicating that self-employment is an intermediate state in the labor market. These transition probabilities hover around 0.08 in a zigzag, albeit decreasing pattern. The transition probabilities from self-employment to unemployment remain low and, in a way, they follow the ups and downs of the business cycle.

In [Figures 5 - 7](#) we present the same transition probabilities for immigrants only, and in [Figures 8 - 10](#) those of the Germans for comparative purposes. [Figures 5 and 8](#) clearly show that the probabilities to move from paid employment to self-employment are very low and exhibit little variation. In 1988, there were even no self-employment transitions for immigrants. The transitions to self-employment are always somewhat higher for Germans than for immigrants throughout the period of analysis. The probabilities to move from employment to unemployment are a lot higher, and in the 1990s they increase to higher levels for the immigrants and become more varying for the Germans. The observed rise in the transition probabilities is much stronger for the migrants. This implies that the rise in the transitions from employment to unemployment is largely an issue of the immigrants and not of the natives.

[Figures 6 and 9](#) verify that, although there is some strong movement between unemployment and employment, in the 1990s immigrants and Germans tend to enter employment much less than in the 1980s. This tendency is even more marked for immigrants. With regards to the transitions into self-employment, immigrants sometimes use self-employment as a way to circumvent unemployment but do not stay in self-employment for long; a similar pattern can be observed for the Germans, although at a higher level of activity. [Figures 7 and 10](#) display the

transition probabilities from self-employment to both employment and unemployment. Once again, there is pronounced entry and exit between self-employment and paid employment, although at a very much higher level and amplitude for the immigrants than for the Germans. The intense zigzag pattern shows that immigrants gladly exit self-employment to go into paid employment and stay for longer periods in paid employment. While the zigzag pattern is also present in the native sample (see [Figure 10](#)), the average size of the transition probability is much larger and the zigzag is much more marked for the migrants than for the sample of the Germans. Overall, the transition probabilities are, however, decreasing over the years. While the probabilities from self-employment to unemployment are lower, [Figures 7 and 10](#) show that there is movement between the two states and immigrants fall into unemployment from self-employment more often than the Germans.

5. Econometric Results

The findings of our conditional logit models are presented in [Table 5](#) for the employed, in [Table 6](#) for the unemployed, and in [Table 7](#) for the self-employed. The reference alternative in these estimations is always the status of the individuals in the previous period. Hence, [Table 5](#) contains the results for the transitions from employment to unemployment and from employment to self-employment, while the transition from employment to employment is the reference state. [Table 6](#) provides the evidence of the transitions into employment and self-employment from the status of being unemployed; staying unemployed is the reference state. The probabilities of moving from self-employment to either employment or unemployment are presented in [Table 7](#); staying in self-employment from one period to the next is the reference state. All tables contain the parameter estimates, the marginal effects, and the respective robust standard errors. The summary of our findings below concentrates on those estimates that are statistically significant at conventional levels. Further, note that the constants in the logit regressions represent the independent parts in the transition probabilities. A negative coefficient suggests a small base transition probability, while a positive coefficient represents a large base transition probability.

Age and age squared have a significant impact on most of the elements of the transition matrix, and the findings are rather plausible. The inflow into unemployment from employment is U-shaped, being high for lower and higher age levels, and increases with age out of employment into self-employment, although at a declining rate. The outflow from unemployment into employment or self-employment is increasing with age at a slowing speed. While older individuals are more likely to move into employment or self-employment from unemployment, this increase becomes smaller through time. However, the mobility from self-employment to employment is U-shaped, implying that middle-age individuals are less likely to change from the self-employment status to employment compared to the younger and older individuals. The transition from self-employment into unemployment rises with age, although at a declining rate.

The impaired health status is significant only in the transitions from employment to unemployment and back. Both cases show that men in Germany with some disability have a higher probability to move into unemployment when they are working, and a lower probability to move into employment when they are unemployed. This shows that men with disabilities are more likely to become and remain unemployed. However, this does not affect the self-employment probabilities.

Education in Germany exhibits only a rather limited impact on the transitions. Both vocational training and higher education reduce the probability of moving out of employment and into unemployment, a result that has been obtained often in similar ways in the literature. Vocational training has also a positive impact on the probability to move back into employment from the status of unemployment or self-employment. Finally, higher educated people are more easily drawn into self-employment when they are unemployed.

Men who own their dwelling are less likely to move from employment to unemployment, but are more likely to take up self-employment when they are unemployed. Family status and the presence of young children are not of much relevance for the transitions. Being married reduces the

probability to become unemployed when previously employed, which is a well-known finding in the literature.

Are entrepreneurial talents inherited? If the father has been self-employed, his son is more likely than others to move into self-employment from a previous unemployment state. Likewise, men with a self-employed father are more likely to make the transition from employment to self-employment. These results indicate that intergenerational transmission provides a positive thrust into self-employment, while it does not exert any influence in the exit from self-employment. However, self-employed fathers also increase the probability to make the transition from employment to unemployment.

Are immigrants different than natives? They are in many ways. Surprising, at least at first sight, are the effects of education acquired in the home country: men with such an education are more likely observed to move from employment to unemployment, and less likely to change from unemployment to employment or self-employment. Education in the home country then indicates a negative signal to the labor market. This is easily explained. Most of those immigrants educated in their home countries came to Germany at the early stages of their career under the guestworker regime. However, their particular education acquired is now no longer needed in the German labor market. Hence, the negative signaling effect.

Compared to natives, Turks are more likely to move from employment to unemployment when employed. They are also more likely to move from unemployment to self-employment when unemployed. Once self-employed, Turks have an increased probability to switch to paid employment, as they also have an enormously high probability to become unemployed. This probably indicates that while Turks are trying to stay in the labor force through self-employment, the success rate of their businesses is low. Other foreigner groups (EU and ex-Yugoslavs) are not different than natives in their transitions from employment to unemployment or self-employment. However, they are much more likely than natives to move into employment and especially self-employment (except ex-Yugoslavs) when previously unemployed. The ex-Yugoslavs also change

more often from self-employment to employment than native Germans. Immigrants from other EU countries move in a very strong way from self-employment to unemployment when compared to natives. Hence, migrants take a significant part of the fluctuations observed between the various employment states with Turks being hit the most, ex-Yugoslavs being in stable paid employment and the EU migrants in between.

Years since immigration is of limited relevance, but nevertheless important. Migrants escape from unemployment to move into self-employment the longer they have been in the country. Furthermore, the relationship between years since immigration and a move from self-employment into employment is also U-shaped: This implies that immigrants first start as self-employed, but change soon into paid employment. Migrants with a longer stay in Germany first exhibit a decline in the transition probability from self-employment to employment, which only rises again with longer durations in the country.

The results further indicate that the employment state vector is moving considerably with waves in the macro economy. Transitions from employment to unemployment are strongly reduced in periods of high growth rates; in expansion periods the previously unemployed move strongly out of unemployment into employment or self-employment; and a boom allows self-employed individuals to move back into employment. Further, the increase in the movements from unemployment to employment is substantially larger for immigrants than for natives during good economic periods.

These findings are rather stable when the entire sample is split into the two subsamples of the Germans and the immigrants, and the analysis is replicated. The respective estimates are provided in the Appendix; there are hardly any marked differences when one compares Tables 5 - 7 to Tables 1A - 3A and Tables 1B - 3B. Simple χ^2 - tests of sample separation suggest that the parsimonious specifications in Tables 5 - 7 are not less powerful than the general specifications in the Appendix. The interaction variable between GNP growth and the immigration dummy in Tables

5 - 7 mimic well the differences between immigrants and Germans in Tables 1A - 3A and Tables 1B - 3B respectively.

The few differences between both subgroups that are not evident from Tables 5 - 7 are: Being married and having vocational training have a stronger moderating effect on the transition from employment to unemployment for the Germans in comparison to the immigrants. Immigrants with a self-employed father exhibit a larger transition probability from employment to unemployment and self-employment than Germans. Children are also a deterrent to move to self-employment from employment for immigrant men. The mobility from unemployment to self-employment is positive and significant for those German men whose father is self-employed (and negative and significant for disabled individuals), but these regressors are insignificant for the immigrants. Once again, immigrant men with children are less likely to go into self-employment from the unemployment state.

6. Summary and Conclusions

In this paper we use a unique data set constructed from 19 waves of the German Socio-economic Panel to study transitions between the states of employment, unemployment and self-employment. Unlike other studies, we provide a link between these transitions and the business cycle, as measured by the GNP growth rates. We find that a Markovian modeling framework suits the data well, and allows us to investigate the labor market dynamics. The transition probabilities are found to be explained well by individual determinants like age, education, home ownership, family characteristics, the self-employment status of the father, various measures to capture differences between migrants and the natives and the business cycle. Self-employment is identified to be an important channel to escape unemployment, and this is a relevant and applicable strategy especially for migrants. However, the outflow out of unemployment is more marked the stronger the economy grows. At the same time, there is a strong permanent outflow of people from self-employment into paid employment. Here, migrants have a larger transition probability than natives. Finally, the

process to move from self-employment to employment is fueled by economic growth, suggesting counter cyclical patterns. The self-employment probabilities of immigrants are rather a function of non cyclical factors such as technological changes and increasing out-sourcing options.

The first row pertains to the entire sample.

The upper triangle pertains to the German sample.

The lower triangle pertains to the immigrant sample.

Note: P₀₁ is the transition from employment to unemployment

P₀₂ is the transition from employment to self-employment

P₁₀ is the transition from unemployment to employment

P₁₂ is the transition from unemployment to self-employment

P₂₀ is the transition from self-employment to employment

P₂₁ is the transition from self-employment to unemployment
