The Institute for the Study of Labor (IZA) in Bonn is a local and virtual international research center and a place of communication between science, politics and business. IZA is an independent nonprofit organization supported by Deutsche Post Foundation. The center is associated with the University of Bonn and offers a stimulating research environment through its international network, workshops and conferences, data service, project support, research visits and doctoral program. IZA engages in (i) original and internationally competitive research in all fields of labor economics, (ii) development of policy concepts, and (iii) dissemination of research results and concepts to the interested public.

IZA Discussion Papers often represent preliminary work and are circulated to encourage discussion. Citation of such a paper should account for its provisional character. A revised version may be available directly from the author.

## ABSTRACT

### **A Simple Theory of Optimal Redistributive Taxation with Equilibrium Unemployment<sup>\*</sup>**

We propose a canonical model of optimal nonlinear redistributive taxation with matching unemployment. In our model, agents are endowed with different skill levels and labor markets are perfectly segmented by skill. The government only observes negotiated wages. More progressive taxation leads to wage moderation that boosts labor demand. We design the optimal nonlinear redistributive tax schedule in the absence of welfare benefits and extensive labor supply margin. Compared to their efficient values, at the optimum gross wages and unemployment are lower. Average tax rates are moreover increasing in wages. The robustness of these properties is also discussed.

# 1 Introduction

Since Mirrlees (1971), the theory of optimal income taxation considers the design of the optimal redistributive policy when the government cannot condition taxes on (exogenous) skills but only on (endogenous) earnings. The theory considers perfect frictionless labor markets, and ignores in particular the possible emergence of (involuntary) unemployment.<sup>1</sup> However, many studies emphasize the deep impact of labor market taxation on employment (e.g. Prescott (2004), Rogerson (2006)) and more specifically on unemployment (Daveri and Tabellini (2000) and Nickell, Nunziata and Ochel (2005)). Moreover, unemployment, and not only low ability, is an important source of poverty. A more comprehensive theory of optimal redistribution should thus be developed in an environment where unemployment is a genuine phenomenon affected by taxation.

In labor market models that take unemployment into account, the level of employment is determined by labor demand, which is a decreasing function of the pre-tax wage. In a non-competitive wage-setting and when the intensive margin (the hours-of-work decision) of labor supply is omitted, a change in tax policy that increases the marginal tax rate without affecting the level of the tax reduces the pre-tax wage, thereby increasing labor demand and reducing unemployment. This is what we call the *wage-cum-labor-demand* margin. Intuitively, such a tax change induces that a given increase in the negotiated post-taxed wage is more costly for the employers. Consequently, they become more reluctant to concede workers' wage claims. On the contrary, a tax change that increases the level of tax while keeping the marginal

tax unchanged increases labor cost, thereby unemployment. These properties have been demonstrated in various theoretical settings: the monopoly union model (Hersoug, 1984), the right-to manage union model (Lockwood and Manning, 1993), the matching model (Pissarides, 1998) and the efficiency wage model (Pisauro, 1991). Empirical evidence that suggests the importance of these effects has also been put forward in the literature (Manning (1993), Røed and Strøm (2002) or Sørensen (1997)). The effect of the marginal tax rate on pre-tax wages obtained in these model is also consistent with the empirical findings on the elasticity of income with respect to the marginal tax rate surveyed by Saez *et alii* (2009). According to them, the most plausible estimates for the elasticity of earnings to one minus the marginal tax rate range from 0.12 to 0.4 in the U.S. Whether this elasticity is due to a labor supply response (as in a Mirrleesian model), to a non-competitive wage setting response or to tax avoidance has, to our knowledge, not been investigated yet, and remains an open empirical issue.

Boone and Bovenberg (2004) have made a distinction between unemployment and non-participation in an optimal redistributive taxation framework where the government does not observe the skill level of the agents. However the unemployment risk does depend nor on wages nor on taxation in their model. Engström (2009) extends the Stiglitz (1982) two-skill model of optimal taxation by introducing search unemployment, but with exogenous hourly wages. Three recent papers (Hungerbühler *et alii* (2006, henceforth HLPV), Hungerbühler and Lehmann (2009, henceforth HL) and Lehmann *et alii* (2009, henceforth LPV)) propose a theory of optimal redistributive taxation with an endogenous risk of being unemployed. In these models, the

deadweight losses of redistributive taxation are due to responses along the wage-cum-labor-demand margin and not the intensive labor supply margin. This chapter proposes a canonical model of optimal redistribution with unemployment. The model in the next section aims at shedding light on the different mechanisms at work. We ignore participation decisions and welfare benefits. The section emphasizes also the methodological differences and analogies between our simple model and a version of the Mirrlees model that generates the same responses of pre-tax earnings to taxation. The concluding section discusses the influence of our simplifying assumptions on the results, and discusses how the above-mentioned papers are related to our canonical model.

## 2 The canonical model

### 2.1 Environment

We consider an economy where risk-neutral individuals are endowed with different skill (ability) levels denoted  $a$ . The exogenous skill distribution is given by the continuous density function  $f(a)$ , defined on the support  $[a_0, a_1]$ , with  $0 < a_0 < a_1 \leq +\infty$ . The size of the population is normalized to 1. Jobs are skill-specific. A worker of skill  $a$  produces  $a$  units of output if and only if she is employed in a type- $a$  job, otherwise her production is nil. This assumption of perfect segmentation is made for tractability and seems more realistic than the polar one of a unique labor market for all skill levels.

The government observes only whether an individual is employed or not,

and if she is, at which wage. The government in particular does neither observe skills nor the recruiting processes. Hence, taxation is only a function of wages. A worker of skill  $a$  gets a (pre-tax) wage  $w_a$  and a disposable income  $c_a = w_a - T(w_a)$  if she is employed. Otherwise, she has no income.

On the skill- $a$  labor market, only a fraction  $L(a, w_a)$  of the  $f(a)$  skill- $a$  individuals find a job. The function  $L(., .)$  summarizes all the ingredients of the labor demand behavior needed for our optimal tax theory. The matching unemployment theory of Mortensen and Pissarides (1999) and Pissarides (2000) provide some micro-foundations for this function. Matching frictions imply that not all individuals find a job and not all firms find a worker. A zero-profit condition determines the number of vacancies created by firms, thereby the labor demand function  $L(., .)$  on each skill-specific labor market. Firms create vacancies until the cost of creating an additional vacancy is lower than the expected gain of filling it. As firms open more vacant jobs, congestion externalities decrease the probability for each vacancy to be filled, thereby the expected profit per vacancy. When wages decrease on skill- $a$  labor market, filling a job generates higher profits and firms create more vacancies. Lemma 1 in LPV shows that it is equivalent to specify a labor demand function  $L(., .)$  or to specify the underlying matching environment. Using this equivalence, we specify here the assumptions of the model in terms of the function  $L(., .)$ .

**Assumption 1**  $L(., .)$  is defined for skill levels  $a \in [a_0, a_1]$  and for wages  $w \in [0, a]$ , takes values within  $[0, 1)$  and satisfies the following conditions:

- i)  $L(., .)$  is decreasing in wages  $w$ .

*ii)  $L(.,.)$  is increasing in skill  $a$ .*

*iii) The wage elasticity  $\partial \log L(a, w) / \partial \log w$  is decreasing in wages.*

*iv) The wage elasticity  $\partial \log L(a, w) / \partial \log w$  is increasing in skill.*

Part *i)* states that employment is decreasing in wages  $w$ . According to Part *ii)*, more productive workers find a job more easily for a given wage level. Part *iii)* and *iv)* imply that employment is more sensitive to wage changes (in terms of elasticity) at high wages and at low productivity levels. These conditions on  $L(.,.)$  are not very restrictive and might seem quite natural to make. This assumption allows a wide range of functions, for instance the linear employment function  $L(a, w_a) = \frac{a-w_a}{a}$ .

We next describe wage setting. On each skill-specific labor market, we assume that the wage maximizes the “wage-setting objective”

$$\mathcal{U}(c, w, a) \stackrel{\text{def}}{=} c \cdot L(a, w) \tag{1}$$

Thus,

$$w_a = \arg \max_w (w - T(w)) \cdot L(a, w) \tag{2}$$

The wage-setting objective  $\mathcal{U}(.,.,.)$  is skill-specific, increasing in disposable income  $c$  ( an employee’s welfare depends positively on the after-tax wage) and decreasing in the pre-tax wage  $w$  ( a higher pre-tax wage reduces firms’ profit and thus labor demand). Various microfoundations can justify the functional specification of this wage-setting objective. As in Mirrlees, we focus on redistribution and consider a setting such that the role of taxation is only to redistribute income and not to restore efficiency (see section

3.3 and HL for a case where the no-tax economy is inefficient). To obtain this property, the matching literature typically assumes that wages are the outcome of a Nash bargain and that the workers' bargaining power satisfies the so-called Hosios (1990) condition.<sup>2</sup> Alternatively, the Competitive Search Equilibrium of Moen (1997) leads also to (2) when search is directed by wages and by skill. Still another possibility is to assume that a skill-specific utilitarian monopoly union selects the wage  $w_a$  before firms decide about vacancy creation (see Mortensen and Pissarides, 1999).

The first-order condition of (2) writes

$$-\frac{\partial \log L}{\partial \log w}(a, w_a) = \eta(w_a) \quad (3)$$

where

$$\eta(w) \stackrel{\text{def}}{=} \frac{1 - T'(w)}{1 - \frac{T(w)}{w}} = \frac{\partial \log(w - T(w))}{\partial \log w} \quad (4)$$

When the pre-tax wage increases by one percent, the term  $\partial \log L / \partial \log w$  measures the relative decrease in employment, while  $\eta(w)$  measures the relative increase in disposable income. At equilibrium, Equation (3) requires that these two relative changes cancel each other out. The elasticity  $\eta(w)$  of disposable income with respect to the pre-tax wage summarizes how the tax system affects the equilibrium wage.<sup>3</sup> A decrease in  $\eta(w_a)$ , either due to a higher marginal tax rate or to a lower average tax rate, induces that a given increase in the pre-tax wage leads to a smaller increase in disposable income. Higher employment probability is then substituted for lower disposable income in the wage-setting process and so the pre-tax wage sinks.

We finally describe the government's budget constraint. Each of the

$L(a, w_a) \cdot f(a)$  employed workers of skill  $a$  pays an amount  $w_a - c_a$  of taxes.

Let

$$U_a \stackrel{\text{def}}{\equiv} \max_w \mathcal{U}(w - T(w), w, a) \equiv (w - T(w)) \cdot L(a, w) \quad (5)$$

be the value of the maximized wage-setting objective for workers of skill  $a$ .

Hence,  $U_a = c_a \cdot L(a, w_a)$  and the government's budget constraint<sup>4</sup> writes

$$\int_{a_0}^{a_1} [w_a \cdot L(a, w_a) - U_a] \cdot f(a) \cdot da = 0 \quad (6)$$

Given the unemployment uncertainty, individuals of skill  $a$  get *on average* a pre-tax wage  $w_a \cdot L(a, w_a)$  and an after-tax income  $U_a$ . Multiplying the difference between the two by the density of workers and taking the sum for all skill levels gives the government's aggregate revenue.

## 2.2 Comparison with a Mirrleesian environment

In the “frictional” environment described above, the pre-tax wage decreases with marginal tax rates. This is because the pre-tax wage maximizes a wage-setting objective that is increasing in disposable income  $c$  and decreasing in pre-tax wage  $w$ . The same property holds in a “Mirrleesian” environment characterized by no frictions on the labor market, an infinitely elastic labor demand and labor supply responses along the intensive margin. In this classical framework, a higher pre-tax wage is due to more effort (less leisure). Conversely, a higher disposable income increases consumption and pushes up utility. Therefore, there exist specifications of individuals' preferences in the Mirrleesian environment that induce the same responses of pre-tax wages to

taxation as our frictional environment. Let  $h$  denote working time. An individual of skill  $a$  working  $h$  earns  $w = a \cdot h$ . Consider then preferences that are linear in consumption with a multiplicatively separable and skill-specific utility of leisure  $v(.,.)$ . So, the utility function equals  $c \cdot v(a, h)$ . These preferences can be rewritten as a function of the observables  $c$  and  $w$  using  $w = a \cdot h$ :

$$\mathcal{U}^M(c, w, a) \stackrel{\text{def}}{=} c \cdot L(a, w) \quad (7)$$

where  $L(a, w) \stackrel{\text{def}}{=} v(a, \frac{w}{a})$ . Equations (1) and (7) have the same form but the economic interpretation of the function  $L(.,.)$  is different. In the frictional environment,  $L(.,.)$  stands for the probability that an individual of skill  $a$  is employed, whereas in the Mirrleesian environment it captures the utility of leisure. In both environments, equilibrium wages maximize  $(w - T(w)) \cdot L(a, w)$ , thereby generating identical responses of wages to taxation. The different economic interpretation of  $L(.,.)$  has a crucial consequence: the deadweight losses of taxation are different. To understand this difference, define

$$U_a^M \stackrel{\text{def}}{=} \max_w \mathcal{U}^M(w - T(w), w, a)$$

as the value of the wage-setting objective for workers of skill  $a$  in the Mirrleesian environment. Hence, disposable income verifies  $c_a = U_a^M / L(a, w_a)$ . Each individual of skill  $a$  pays taxes  $w_a - (U_a^M / L(a, w_a))$  and the government's budget constraint writes

$$\int_{a_0}^{a_1} \left[ w_a - \frac{U_a^M}{L(a, w_a)} \right] \cdot f(a) \cdot da = 0$$

In this environment, deadweight losses are minimized whenever wages  $w_a$  maximize tax revenues per individual of skill  $a$  for a given value of the wage-setting objective. In the Mirrleesian environment, efficiency, i.e. the situation where deadweight losses are minimized, requires a zero marginal tax rate.<sup>5</sup>

In the frictional environment, a change in wages affects the level of taxes paid by employed workers,  $w_a - \frac{U_a}{L(a, w_a)}$ , exactly as in the Mirrleesian environment. However, it also affects the fraction of taxpayers  $L(a, w_a)$ . Hence, expected tax revenues per individual of skill  $a$  equal  $w_a L(a, w_a) - U_a$ . So, the deadweight losses associated to taxation are minimized whenever the average pre-tax wage  $w_a L(a, w_a)$  per individual of skill  $a$  is maximized. Efficiency therefore requires that the elasticity  $\eta(w_a)$  of disposable income with respect to wages is equal to 1, that is the marginal tax rate is equal to the average tax rate (see Equation (4)). Consequently, when the average tax rate is positive (negative), the efficient level of the marginal tax rate is also positive (negative).

### 2.3 Social optimum

We henceforth only consider the frictional environment. The government is ready to compensate individuals for their innate heterogeneous ability. To formalize this idea, we consider a social objective which consists in an increasing and concave transformation of individuals' skill-specific expected utility  $U_a$ :

$$\Omega = \int_{a_0}^{a_1} \Phi(U_a) f(a) da \quad (8)$$

The government aims at maximizing its objective subject to the budget constraint (6) and the choices made by the agents. The government does not observe the productivity of each job but only the wage negotiated by each worker-firm pair. Since a worker-firm pair maximizes the wage-setting objective  $\mathcal{U}(c, w, a)$  that is increasing in  $c$ , one can apply the Mirrleesian methodology to solve the optimal tax problem.

The *taxation principle* (Hammond 1979, Rochet 1985 and Guesnerie 1995) applies. So, the set of allocations induced by a tax system  $T(\cdot)$  through the wage-setting equations (2) corresponds to the set of incentive-compatible allocations  $\{w_a, c_a, U_a\}_{a \in [a_0, a_1]}$  that verify

$$\forall (a, b) \in [a_0, a_1]^2 \quad \mathcal{U}(c_a, w_a, a) \geq \mathcal{U}(c_b, w_b, a) \quad (9)$$

This condition expresses that a worker-firm pair of type  $a$  chooses the bundle  $(w_a, c_a)$  designed for her, rather than any other bundle  $(w_b, c_b)$  designed for worker-firm pairs of any other type  $b$ . From Assumption 1 *iv*), the strict single-crossing condition holds. Hence, (9) is equivalent to the envelope condition associated to (2)

$$\dot{U}_a = U_a \cdot \frac{\partial \log L}{\partial a}(a, w_a) \quad (10)$$

and the monotonicity requirement that the wage  $w_a$  is a nondecreasing function of the skill level  $a$ . We consider the so-called first-order approach that considers the “relaxed” problem without the monotonicity constraint.<sup>6</sup>

Hence, the government’s problem consists in finding an allocation  $a \mapsto$

$\{w_a, U_a\}$  that maximizes the social objective (8) subject to the government's budget constraint (6) and the incentive constraint (10). Taking the wage as the control variable and the expected utility as the state variable,<sup>7</sup> the optimal tax problem can be solved using the Hamiltonian

$$\mathcal{H}(w, U, a, \lambda, q) \stackrel{\text{def}}{=} \{\Phi(U) + \lambda[w \cdot L(a, w) - U]\} f(a) + q \cdot U \cdot \frac{\partial \log L}{\partial a}(a, w)$$

where  $\lambda$  is the multiplier associated to the government's budget constraint and  $q$  is the co-state variable associated to the incentive constraint. It is convenient to use  $Z_a = -(q_a \cdot U_a) / \lambda$ . Then the first-order conditions of the government's problem are (10) and

$$\frac{\partial (w_a L(a, w_a))}{\partial w} \cdot f(a) = \frac{\partial^2 \log L}{\partial a \partial w}(a, w_a) \cdot Z_a \quad (11a)$$

$$-\dot{Z}_a = \left(1 - \frac{\Phi'(U_a)}{\lambda}\right) \cdot U_a \cdot f(a) \quad (11b)$$

$$Z_{a_1} = 0 \quad (11c)$$

$$Z_{a_0} = 0 \quad (11d)$$

Combining (11b) and (11c) gives

$$Z_a = \int_a^{a_1} \left(1 - \frac{\Phi'(U_t)}{\lambda}\right) \cdot U_t \cdot f(t) \cdot dt \quad (12)$$

These relations describe the equity-efficiency tradeoff made by the government. To see the intuition behind this optimality condition, we focus on the optimization problem for agents of type  $a$  and consider a marginal increase in their wage. The incentive constraint (10) implies that the value

of the wage-setting objective for workers of skill  $a$ ,  $U_a$ , is predetermined and not affected by the change in the wage  $w_a$ .

The left-hand side of Equation (11a) stands for the *efficiency* part of the trade-off. An increase in the wage rate  $w_a$  decreases the probability of being employed, so the impact on the average pre-tax wage  $w_a L(a, w_a)$  per individual of skill  $a$  is ambiguous.

The right-hand side of Equation (11a) represents the impact on *informational rents* of a higher pre-tax wage for type- $a$  workers. When jobs of productivity  $a$  are better paid (while keeping  $U_a$  fixed), a wage-setter of type  $t > a$  finds it profitable to choose the wage  $w_a$  designed for type- $a$  jobs instead of the wage  $w_t$  designed for her. To prevent this “mimicking”, the value of the wage-setting objective for type- $t$  jobs has to grow. Using Equation (10), the term in front of  $Z_a$  on the right-hand side of (11a) measures by how much the rate of change of the skill-specific value of the wage-setting objective  $\dot{U}_a/U_a$  has to grow when  $w_a$  marginally increases. From Assumption 1 *iv*), this term is positive.

The incentive-compatibility constraints will remain satisfied if all jobs with a productivity higher than  $a$  benefit from an equivalent *relative* increase in their wage-setting objective. For any type  $t$  above  $a$ , this relative increase times  $U_t$  gives the rise in the wage-setting objective. Each unit of the latter generates an increase in the social welfare measured by  $\Phi'_t$  and implies a budgetary cost equal to  $\lambda$ . Aggregating these two terms between  $a$  and  $a_1$  and dividing by the cost of public funds gives (12).

The intuition behind Equation (11d) is the following. A unit relative increase of the wage-setting objective spills over the whole skill distribution

and its effect is proportional to  $Z_{a_0}$ . At the optimum, this change must have no first-order effect, so  $Z_{a_0}$  has to equal zero.

We henceforth use the words “optimal - optimality” to characterize the solution to the government’s problem. We get the following proposition:

**Proposition 1** *i) For each  $a \in (a_0, a_1)$ , optimal wages are below their efficient levels.*

*ii) Optimal and efficient wages coincide at both ends of the skill distribution.*

**Proof.** By Assumption 1 *ii)* and Equation (10),  $U_a$  is increasing in  $a$ , and  $1 - \frac{\Phi'(U_a)}{\lambda}$  is thus also increasing in  $a$ . Moreover, from Equations (11c) and (11d), the mean value theorem ensures the existence of a critical skill level  $\hat{a}$  such that  $\dot{Z}_{\hat{a}} = 0$ , which by Equation (11b) implies that  $1 - \frac{\Phi'(U_{\hat{a}})}{\lambda} = 0$ . So, from (11b), Function  $a \mapsto Z_a$  is increasing on  $[a_0, \hat{a}]$  and decreasing on  $[\hat{a}, a_1]$ . It thus take positive values on  $(a_0, a_1)$  and is nil at  $a = a_0, a_1$ . Using Equation (11a) and Assumption 1 *iii)* ends the proof. ■

The intuition of Proposition 1 is that the government wants to avoid informational rents, because those rents benefit to high-skilled jobs. Distorting wages below their efficient levels is the only way the government can do this. The optimum trades off the equity gains of reducing informational rents against the efficiency losses of distorting “optimal” wages below their “efficient” levels. At both ends of the skill distribution, the equity gain is nullified, so wages are not distorted. Proposition 1 implies the three following corollaries.

**Corollary 1** *i) For each  $a \in (a_0, a_1)$ , the optimal probability of being employed,  $L(a, w_a)$ , is above its efficient level.*

*ii) Optimal and efficient probabilities of being employed coincide at both ends of the skill distribution. Aggregate employment is above its efficient level.*

This follows directly from Proposition 1 since the skill-specific employment probability is decreasing in the skill-specific wage (by Assumption 1 *i*). Finally,

**Corollary 2** *The average tax rate is increasing along the whole wage distribution.*

**Proof.** From the first-order condition (3) of the wage-setting program, the optimal allocation where wages are below their efficient value can only be decentralized by implementing a tax schedule such that the elasticity  $\eta(w)$  of disposable income with respect to wages is below 1. From (4), this implies that for all wage levels (except for  $w_0$  and  $w_1$ ) the marginal tax rate  $T'(w)$  is above the average tax rate  $T(w)/w$ . Hence the optimal average tax rate is increasing in the wage. ■

In other words, the optimal allocation is implemented by a progressive (in the sense of increasing average tax rates) tax schedule because progressivity reduces wages below their efficient levels.

**Corollary 3** *If the skill distribution is bounded, the marginal tax rate is positive at the top.*

**Proof.** According to Point *ii*) of Proposition 1, at the highest skill level, the optimal wage is efficient. So, from the first-order condition (3) of the wage-setting program one must have  $\eta(w_{a_1}) = 1$ . From (4), this implies that  $T'(w_{a_1}) = \frac{T(w_{a_1})}{w_{a_1}}$ . These rates are positive by the budget constraint (6) and Corollary 2. ■

### 3 Extensions

This Section investigates to which extent our canonical model of optimal redistribution with endogenous unemployment is affected when some assumptions are relaxed. It builds on the results of HLPV, HL and LPV.

#### 3.1 Assistance benefits

Our simple model postulates that the unemployed get no income. This assumption is not consistent with the fact that the government aims at redistributing to the poor. It is therefore necessary to introduce unemployment benefits. However, as the model is static, the government is unable to infer the type of a jobless individual from her past earnings. Thus, we focus on an assistance benefit, i.e. a benefit that is the same for unemployed agents, whatever their skill level. Although redistribution is made through a high assistance benefit and the surplus of workers is reduced, the results obtained in the previous section are still valid.

However, the invariance of the results can be explained by the fact that redistributing through a high assistance benefit has no efficiency effect since no participation decision is taken into account. HLPV consider an endogenous

participation. For simplicity, they assume that all individuals face the same cost of participation, whatever their skill level. Consequently, every agent above (below) an endogenous threshold of skill participates (does not participate). Moreover, they assume that the government is unable to screen the search activities of the unemployed. Therefore, the government is constrained to give the same level of assistance benefit to all non-employed individuals, whatever their skill or their participation decisions. In this environment, HLPV show that for all participating types, point *i*) of Proposition 1 and of Corollary 1, and Corollary 2 still hold. Point *ii*) of Proposition 1 and of Corollary 1 do not hold anymore for the lowest skill  $a_0$ . This is because they do not participate anymore. The government chooses to reduce efficiency by pushing down participation because it allows her to reduce the informational rents given to the more productive worker-firm pairs. Moreover, in order to reduce participation, in-work benefits (if any) are lower than assistance benefits.

### **3.2 The extensive margin of the labor supply**

As is shown in many empirical studies (e.g. Meghir and Phillips (2008)), labor supply is particularly responsive to taxation on its extensive margin (the decision to participate or not on the labor market). Moreover, theoretical papers have emphasized that in an optimal redistribution framework without (involuntary) unemployment, the tax schedule properties are crucially affected by the introduction of an endogenous extensive margin (Diamond (1980), Saez (2002) and Choné and Laroque (2005)).

The inclusion of participation responses in HLPV is not satisfying since the elasticity of participation is infinite at a threshold skill and zero above. Assuming that the cost of participation varies both within and between skill levels, LPV provide a much more general treatment of participation. In the classical theory of unemployment,<sup>8</sup> the employment level is solely determined by labor demand, an unrealistic property according to empirical findings. Conversely, in LPV, both labor supply and labor demand determine the equilibrium level of employment through the matching function. LPV show that point *i*) of Proposition 1 and of Corollary 1 and Corollary 2 hold if the government has a Maximin objective and the elasticity of participation decreases in skill (the most plausible case according to empirical evidences, see Juhn *et alii* (1991), Immervoll *et alii* (2007) or Meghir and Phillips (2008)). If the government has a more general social objective, no analytical result can be put forward. However, LPV suggest that points *i*) of Proposition 1 and of Corollary 1 still hold. The most important difference with the results of HLPV under a general social objective concerns participation and the tax schedule. While HLPV show that marginal tax rates are positive everywhere and a higher transfer to low-skilled workers than to the non-employed is never optimal (no EITC), a more general treatment of participation decisions appears to be compatible with negative marginal rates and an EITC for the low skilled. Thus, upward distortions of the low skilled individuals' participation rates can be optimal.

### 3.3 Inefficiency of the no-tax economy

In order to focus on redistributive issues, our canonical model assumes that the no-tax economy is efficient. However, this is a very special case since there is no reason to believe that a decentralized wage setting necessarily maximizes efficiency. HL build on the framework of HLPV but they do not assume that the Hosios condition is satisfied. In the case where the bargaining power of workers is too low, they show that bunching at the bottom of the wage distribution is optimal. This situation suggests that a binding minimum wage can be optimal.

### 3.4 Redistribution within skill groups

Unemployment raises an issue that does not appear in a Mirrleesian framework: the redistribution between employed and unemployed individuals endowed with the same skill. For simplicity, HLPV neglect this issue by considering an *ex-ante* social objective that depends on individuals' expected utility:

$$\int_{a_0}^{a_1} \Phi((w_a - T(w_a)) \cdot L(a, w_a) + b \cdot (1 - L(a, w_a))) \cdot f(a) \cdot da$$

where  $b$  stands for the welfare benefit. Conversely, one can adopt the *ex-post* objective that depends on realized incomes:

$$\int_{a_0}^{a_1} \{L(a, w_a) \cdot \Phi(w_a - T(w_a)) + (1 - L(a, w_a)) \cdot \Phi(b)\} \cdot f(a) \cdot da$$

LPV explains that the adoption of the *ex-post* objective provides an additional motivation to distort wages downwards: a lower wage reduces the income inequality between employed and unemployed individuals of the same skill and increases the number of employed.

### 3.5 Further research

Finally, we expose some potential extensions. First, a dynamic model would enable to introduce earning-related unemployment insurance. Hence, one can expect that a “dynamic optimal taxation” version (à la Golosov *et alii* 2003) of our model would deliver interesting insights about the optimal combination of unemployment insurance and taxation to redistribute income. Second, we have implicitly considered that it is impossible for the government to monitor job-search activity. This is clearly a strong assumption that should be relaxed. Third, we abstract from any response of labor supply along the intensive margin. Although the responses along the extensive margin seem empirically much more important, enriching the framework to include hours of work, in-work effort or educational investment would be interesting. Finally, labor supply decisions are often taken at the household level, not at the individual level (see Kleven *et alii* 2009). An optimal redistributive theory incorporating this issue would thus be more comprehensive.

## Notes

<sup>1</sup>Many international institutions (such as the ILO or the OECD) distinguish among *non-employed* individuals the *unemployed* who search for a job from those *out-of-the-*

labor-force.

<sup>2</sup>Under this condition, the bargaining power of workers equals the elasticity of the matching function with respect to the stock of unemployment.

<sup>3</sup> $\eta(w)$  is the so-called Coefficient of Residual Income Progression.

<sup>4</sup>Introducing an exogenous amount of public expenditure does not change the qualitative results of the model.

<sup>5</sup>Formally, the first-order condition of maximizing  $w_a - \frac{U_a}{L(a, w_a)}$  in  $w_a$  for a given  $U_a$  writes (using  $c_a/w_a = 1 - (T(w_a)/w_a)$ ):

$$\frac{1}{1 - \frac{T}{w}} = - \frac{\partial \log L}{\partial \log w}(a, w_a)$$

which implies  $T'(w_a) = 0$ , given (3).

<sup>6</sup>Simulations in HLPV and LPV verify that along the solutions of the relaxed problem, wages are non-decreasing in skills.

<sup>7</sup>and making the regularity assumption that the control variable is continuous in skill

<sup>8</sup>Which consists in standard labor-supply and labor demand curves and a wage above the market-clearing level.
